

Paper Title: Newton's forward interpolation

Published: Math's Journal

What is Newton's forward interpolation

Newton's forward difference formula is a finite difference identity giving an interpolated value between tabulated points in terms of the first value and the powers of the forward difference.

The formula is particularly useful for interpolating the values of $f(x)$ near the beginning of the set of values given.

Why

Newton's forward and backward interpolation aka Newton Gregory technique are only available for equal intervals. Let's say you have some data with equal interval and you want to find any missing value in these. Then the formula is used.

When?

Newton's forward interpolation technique is to be used when the x - data point is near the beginning. That is, if you have four data points, say $X = 1, 3, 5, 9$ and 10 . If you are looking for value of y at $x = 3$ which is near the beginning of the table, then Newton's forward interpolation works best.

Limitation

If the data has large number of swings, then the relations take unnatural curve. If we calculate a missing value, it will not be accurate.
